10% Ni-doped Sr$_2$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ with A-site deficiency is prepared to induce in situ precipitation of B-site metals under anode conditions in solid oxide fuel cells. XRD, SEM and TEM results show that a significant amount of nano-sized Ni-Fe alloy metal phase has precipitated out from Sr$_2$Fe$_{1.5}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ upon reduction at 800°C in H$_2$. The conductivity of the reduced composite reaches 29 S cm$^{-1}$ at 800°C in H$_2$. Furthermore, fuel cell performance of the composite anode Sr$_1.9$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ is investigated using H$_2$ as fuel and ambient air as oxidant with La$_{0.8}$Sr$_{0.2}$Ga$_{0.87}$Mg$_{0.13}$O$_3$ electrolyte and La$_{0.6}$Sr$_{0.4}$Co$_{0.2}$Fe$_{0.8}$O$_3$ cathode. The cell peak power density reaches 968 mW cm$^{-2}$ at 800°C and the voltage is relatively stable under a constant current load of 0.54 A cm$^{-2}$. After 5 redox cycles of the anode at 800°C, the fuel cell performance doesn’t suffer any degradation, indicating good redox stability of Sr$_1.9$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$. Peak power density of 227 mW cm$^{-2}$ was also obtained when propane is used as fuel. These results indicate that a self-generated metal-ceramic composite can be successfully derived from Sr$_2$Fe$_1.5$Mo$_{0.5}$O$_{6-\delta}$ by compositional modifications and Sr$_1.9$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ is a very promising solid oxide fuel cell anode material with enhanced catalytic activity and inherited good redox stability from the parent ceramic material.

Manuscript submitted November 8, 2013; revised manuscript received December 6, 2013. Published January 1, 2014. This was Paper 760 presented at the San Francisco, CA, Meeting of the Society, October 27–November 1, 2013.

Ceramic anode materials have drawn a lot of attention due to their potentially better stability in different fuels or under redox cycling in solid oxide fuel cells (SOFCs) comparing with the conventional Ni-based cermet anodes. Among the proposed ceramic anode candidates, perovskite-type oxides, such as LaCrO$_3$-based and SrTiO$_3$-based materials, have been intensively studied due to their relatively high mixed conductivity and good stability in reducing atmospheres.1–4 Recently, a new class of Sr$_2$M$_{1.3}$MO$_{6-\delta}$ materials (M = Mn, Fe, Co, Ni, 0 < x < 1) with double perovskite structure have been demonstrated as anode materials for SOFCs.5–8 This type of material has various B-site cation choices in a wide range of compositions, offering flexibility in tuning their properties. Several interesting anode candidates with this structure have been reported with good stability in different fuels and under redox cycling.6,9

Ceramic anode materials exhibit good stability but there are still considerable needs for improving their overall cell performance. One of the limiting properties of these ceramic candidates is their relatively low catalytic activity. Many studies have shown that the fuel cell performance can be dramatically improved by introducing a small amount of metal catalysts to these mixed conductors.10–14 Unlike the cermet materials which require a large volume ratio of the metal phase to provide percolating conductive passage, it is possible to fabricate highly dispersed metal catalyst on the mixed-conducting ceramic backbones. With good mixed conducting properties, the ceramic materials may help stabilizing the metallic catalyst phase, promoting their catalytic activity and eventually mitigating the instability issues that ceramic anodes typically have. Several reports have demonstrated both enhanced activity and stability of the metal modified ceramic anode materials.11,13,14

Regarding the modification method, infiltration is always an easy and effective way to obtain the supported catalysts on porous substrates and many reported metal modified ceramic anodes have been prepared by this approach as mentioned above. Recently, in situ generation of metallic particles from oxides has been considered as an alternative way to obtain the supported metal catalysts in certain oxide material systems.15–19 Compared with the infiltration approach, in situ generation of metal particles is much simpler and is less affected by other factors such as the morphology of the ceramic backbones. The size and loading amount of the metal particles are determined by the chemical properties of the oxides and the metallic catalyst distribution may be more homogeneous since the metals are precipitated directly from the ceramic lattice. Nano-sized Ni, Ru, and Pd particles have been reported to be uniformly dispersed on oxides via reduction of LaCrO$_3$- or NbTiO$_3$-based materials and enhanced fuel cell performance has been observed with these composite anode materials.15–18 By exposing Pr$_{0.4}$Sr$_{0.6}$Co$_{0.2}$Fe$_{0.7}$Nb$_{0.1}$O$_3$ to a reducing environment at 900°C, nano-sized Co-Fe alloy particles supported on a ceramic matrix have been obtained. Besides the enhanced anode activity, an interesting regenerative behavior upon in situ redox cycling has also been achieved in this material system.19

Previously, we have successfully improved Sr$_2$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ anode performance by incorporating a small amount of Ni through infiltration.14,15 Since Ni shows good catalytic activity and can be more easily reduced than Fe, in this study we substitute Fe on the B-site of Sr$_2$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ with 10% Ni and expect to in situ generate metal-ceramic composite anode under the fuel cell operating conditions. By introducing slight A-site deficiency, precipitation of metal particles on the ceramic matrix has been facilitated. The electrochemical performance and stability of the obtained composite anode are systematically studied.

Experimental

Material synthesis.— Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ and Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ were prepared by a combustion process. Stoichiometric amount of (NH$_4$)$_2$MoO$_4$, 4H$_2$O was first dissolved in deionized water. To prepare 0.01 mol of the oxide, 2g of citric acid was then added to the solution as a chelating agent to prevent precipitation of the molybdate salt. Sr(NO$_3$)$_2$, Fe(NO$_3$)$_3$, 9H$_2$O and Ni(NO$_3$)$_2$, 6H$_2$O were then dissolved and a clear yellowish solution was formed. Finally, 15g of glycine was added as a combustion agent and the solution turned dark red. The as-prepared solution was heated by a microwave oven with 1000 W power until self-ignition took place. The ash was then collected and heat-treated at 1100°C in air for 5 h to form the perovskite structure. The interlayer material La$_{0.4}$Ce$_{0.6}$O$_{2-\delta}$ (LDC) and the cathode material La$_{0.6}$Sr$_{0.4}$Co$_{0.2}$Fe$_{0.8}$O$_{3}$ (LSCF) were prepared by a similar citric acid-assisted combustion method. La$_{0.8}$Sr$_{0.2}$Ga$_{0.87}$Mg$_{0.13}$O$_3$ (LSGM) electrolyte powder was synthesized by solid-state reaction.

Characterization.— XRD patterns of the powders were recorded using a D/MAX-3C X-ray diffractometer with graphite-monochromatized Cu Kα radiation (λ = 1.5418 Å). XPS was
Cell fabrication and test.— LSGM powder was pressed into pellets and sintered at 1450 °C for 10 h to form dense electrolyte membranes. Electrode inks and LDC ink were made by mixing the powders with a Heraeus binder V006 at a weight ratio of 1:1.5. The LDC layer to prevent the reaction between LSGM and Ni from the anode was fabricated by painting the LDC ink on the LSGM electrolyte pellet followed by sintering at 1350 °C for 2 h. The anode was then painted on the LDC layer and the cathode was painted on the other side of the LSGM electrolyte pellet. After drying, the electrodes were co-fired in air at 1100 °C for 2 h. Au paste and Pt paste were painted on the anode and cathode, respectively and fired at 1000 °C for 0.5 h to form the current collector. Two wires were connected to each electrode and the cells were tested in a four-probe configuration. The flow rate of the fuel gas was set to 40 mL min⁻¹ and sintered at 1300 °C for 6 h for electrical conductivity measurement. Ag wires and Ag paste were used to attach four probes on the sintered bar sample. The bar with attached Ag wires was dipped onto Holey Carbon 400 mesh Cu grid (Ted Pella, Inc.). JEOL 3000F with a point-to-point resolution of 0.17 nm operating at 300 kV equipped with a Schottky field-emission gun (FEG), calibrated by C 1s at 284.6 eV. SEM images of the powders before and after reduction were evaluated using a Zeiss Ultra plus Thermal Field Emission Scanning Electron Microscope. The metal-ceramic composites were characterized by high-resolution transmission electron microscopy (HRTEM). The powders were dispersed in ethanol and well sonicated before being evaluated using a Zeiss Ultra plus Thermal Field Emission Scanning Electron Microscope. The metal-ceramic composite was synthesized by firing the precursors at 1350 °C for 10 h before the data was collected.

Results and Discussion

Pure cubic perovskite phases of Sr₂Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ and Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ can be obtained by firing the precursors at 1100 °C in air for 5 h. As shown in Figure 1a, no impurity peak was detected in the XRD patterns for both compositions. The only difference is that the XRD peaks of Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ slightly shifted to lower angles as shown in Figure 1b, indicating that the lattice was expanded. The lattice expansion in Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ is consistent with those reported for A-site deficient composites in other systems. The cation deficiency can be accompanied by generating oxygen vacancies and p-type defects in the lattice for charge compensation. The general decrease in oxygen content results in the lattice expansion in these A-site deficient composites. The lattice parameters and crystalline sizes of both samples were calculated by Jade software and listed in Table I. Larger crystalline particles were obtained for Sr₂Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ, indicating the A-site deficient sample is also easier to be sintered, consistent with other reports. The lattice parameter of Sr₂Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ is slightly smaller than that of Sr₂Fe₁.₄Mo₀.₅O₆₋ₓ due to the p-type doping of Ni which also increases the concentration of Fe³⁺, the p-type defects.

In order to verify the impact of p-type doping of Ni on the oxidation state of Fe, XPS was conducted for Sr₂Fe₁.₄Mo₀.₅O₆₋ₓ, Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ, and Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆₋ₓ and the Fe 2p core levels are shown in Figure 2. Previously, the Fe oxidation states in a series of Mo-doped SrFeO₃ systems have been analyzed by fitting Fe 2p 3/2 core-levels. Three interval-fixed peaks, which are assumed to correspond to Fe²⁺, Fe³⁺, and Fe⁴⁺, respectively. The estimated results are well consistent with the observations from neutron diffraction. Considering the similar material compositions, the fitting model was
directly applied in this work as well. The fitting results are shown in Table II. The fitting peak III corresponding to Fe$^{2+}$ is reduced significantly in both Ni-doped samples, indicating a p-type electronic compensation mechanism for Ni-doping and resulting in an increase in the oxidation state of Fe. It can be noted that the oxidation state of Fe is even slightly higher in Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ than in Sr$_{2}$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ due to the partial electronic charge compensation for the cation deficiency as discussed above. According to the average oxidation state of Fe and assuming that Ni$^{2+}$ and Mo$^{6+}$ occur in the oxide in oxidizing atmosphere, the oxygen content for each composition can be estimated and the results are also listed in Table II. The value for Sr$_{2}$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ is consistent with those reported elsewhere.$^{22,23}$ The oxygen content is 5.81 for Sr$_{2}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ and 5.71 for Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$, which are in agreement with our expectations.

Figure 3 shows the XRD patterns of Sr$_{2}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ and Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ after reduction at 800° C in H$_2$ (3vol% H$_2$O) for 10 h. Besides the major perovskite phase, secondary phases were also detected in the reduced samples. By contrast, the un-doped Sr$_2$Fe$_1.5$Mo$_{0.5}$O$_{6-\delta}$ phase formation in Ni-doped Sr$_2$Fe$_{1.5}$Mo$_{0.5}$O$_{6-\delta}$ was detected in both samples after reduction as shown in Figure 3. However, in the stoichiometric composition, once the Ni-Fe phase starts to precipitate, excess Sr on the A-site may cause formation of some Sr-rich phase, shown as a shoulder peak at around 31 degree, which may inhibit further formation of the metal phase. Therefore, the intensity of Ni-Fe alloy phase was very low in Sr$_{2}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ while the metal precipitation is significantly enhanced in Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ with A-site deficiency. The exact composition of the Sr-rich impurity phase was not determined due to the low intensity.

Morphology change upon reduction of Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ was further investigated by SEM. Figure 4a shows the SEM image of Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ after being fired at 1100° C in air. Typical sponge-like powder made by combustion methods with smooth and well crystallized surface can be observed. The powder surface became fairly rough upon reduction as shown in Figure 4b. With an enlarged image and in the areas circled in Figure 4c, it can be seen that a lot of nano-sized metal particles with diameters arranging from 10 to 50 nm have been formed on the surface, as detected by XRD. An SEM image of Sr$_2$Fe$_{1.4}$Mo$_{0.5}$O$_{6-\delta}$ after being reduced under the similar condition is shown in Figure 4d for comparison. No evident surface change can be observed which is consistent with the XRD results in our previous report, indicating the better phase stability of Sr$_2$Fe$_{1.4}$Mo$_{0.5}$O$_{6-\delta}$ in reducing atmosphere.$^6$

In order to verify the metal phase location in reduced Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$, HRTEM was conducted on powders before and after reduction and the images are shown in Figure 5. In

**Figure 3.** XRD pattern of Sr$_{2}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ and Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ after reduction in H$_2$ (3vol% H$_2$O) at 800° C for 10 h.

**Figure 4.** SEM images of (a) Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ synthesized in air, (b), (c) reduced Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6-\delta}$ in different magnifications with some of the particles circled, and (d) Sr$_{2}$Fe$_{1.4}$Mo$_{0.5}$O$_{6-\delta}$ reduced in H$_2$ (3vol% H$_2$O) at 800° C for 10 h.
Figure 5. (a) Bright field TEM image and (b) HRTEM image of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ. (c) Bright field TEM image of reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ, HRTEM image of (d) a typical metal alloy particle and (e) the furry surface of reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ.

accordance with the SEM observation, bright field TEM image of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ before reduction exhibits smooth contours of the particles as seen in Figure 5a. The lattice parameter measured on the HRTEM image in Figure 5b was about 0.276 nm, corresponding to the reflection originating from the perovskite crystal plane (110). Significant morphology change of the reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ is revealed by the furry contours of the powder as shown in the bright field TEM image in Figure 5c. Figure 5d shows the HRTEM image of a typical nano-sized metal alloy particle generated by reduction. The particle size was about 15 nm and the crystal plane (111) of cubic Ni-Fe alloy with d-spacing of 0.207 nm was observed. Figure 5e shows the HRTEM image of the furry surface of the reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ. It can be seen that this layer was composed of smaller particles less than 5 nm. Several small zones showing a d-spacing of 0.178 nm, corresponding to (200) plane of the Ni-Fe alloy phase, can be observed. According to EDS analysis, the Ni/Fe ratio is around 10 at% in the furry surface area, higher than that of 5 at% measured in the region beneath the surface, confirming the precipitation trend of Ni during reduction. Besides the metal alloy phase, crystal grains with d-spacing of 0.295 nm and 0.255 nm were also determined in Figure 5e in the furry surface area. These planes are probably corresponding to (111) and (200) of cubic SrO (JCDPS #48–1477) which was not detected by XRD due to the low content. It can be seen that this layer was composed of smaller particles less than 5 nm. Several small zones showing a d-spacing of 0.178 nm, corresponding to (200) plane of the Ni-Fe alloy phase, can be observed. According to EDS analysis, the Ni/Fe ratio is around 10 at% in the furry surface area, higher than that of 5 at% measured in the region beneath the surface, confirming the precipitation trend of Ni during reduction. Besides the metal alloy phase, crystal grains with d-spacing of 0.295 nm and 0.255 nm were also determined in Figure 5e in the furry surface area. These planes are probably corresponding to (111) and (200) of cubic SrO (JCDPS #48–1477) which was not detected by XRD due to the low content. It suggests that the reduction also caused slight surface decomposition of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ.

Bulk electrical conductivity of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ measured by a dc four-probe method in both air and H2 and the results are compared with that of Sr2Fe1.5Mo0.5O6-δ as the corresponding impedance spectra in Figure 5f. Figure 5g shows the HRTEM image of a typical metal alloy particle generated by reduction. The particle size was about 15 nm and the crystal plane (111) of cubic Ni-Fe alloy with d-spacing of 0.207 nm was observed. Figure 5h shows the HRTEM image of the furry surface of the reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ. It can be seen that this layer was composed of smaller particles less than 5 nm. Several small zones showing a d-spacing of 0.178 nm, corresponding to (200) plane of the Ni-Fe alloy phase, can be observed. According to EDS analysis, the Ni/Fe ratio is around 10 at% in the furry surface area, higher than that of 5 at% measured in the region beneath the surface, confirming the precipitation trend of Ni during reduction. Besides the metal alloy phase, crystal grains with d-spacing of 0.295 nm and 0.255 nm were also determined in Figure 5h in the furry surface area. These planes are probably corresponding to (111) and (200) of cubic SrO (JCDPS #48–1477) which was not detected by XRD due to the low content. It suggests that the reduction also caused slight surface decomposition of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ.

Mo-doped SrFeO3δ shows a p-type conduction behavior in oxidizing atmospheres. Since Ni-doping and Sr-deficiency can all be considered as p-type doping for Sr2Fe1.5Mo0.5O6-δ, improved conductivity of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ was observed below 500°C when the doping was dominantly compensated by electron holes. At higher temperatures, ionic charge compensation by oxygen vacancies started to take effect. Since the oxygen vacancies are easier to form in Sr1.9Fe1.4Ni0.1Mo0.5O6-δ, its conductivity dropped below that of Sr2Fe1.5Mo0.5O6-δ when temperature increased. The comparison of conductivity in air between Sr1.9Fe1.4Ni0.1Mo0.5O6-δ and Sr2Fe1.5Mo0.5O6-δ confirms that Ni was well incorporated into the lattice before reduction. However, Mo-content in the ceramic phase will be beneficial to the n-type conductivity, due to the loss of Fe and Ni from the lattice. Together with the conductive metal phase, the conductivity of reduced Sr1.9Fe1.4Ni0.1Mo0.5O6-δ in H2 was evidently higher than that of Sr2Fe1.5Mo0.5O6-δ. Its electrical conductivity reached 29 S cm⁻¹ at 800°C, which is sufficient for applying this material in a composite anode of SOFCs.

Single cell performance of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ-SDC composite anode was tested on LSGM electrolyte with a LDC interlayer and LSCF cathode. Figure 6 shows the cell performance as well as the corresponding impedance spectra at 750, 800, and 850°C in H2. The peak power density at 800°C reached 968 mW cm⁻² which is evidently higher than that of the cell with Sr2Fe1.5Mo0.5O6-δ or Sr2Fe1.5Mo0.5O6-δ-SDC anodes in similar cell configurations. Such improvement can be attributed to the good catalytic activity of the metal alloy phase formed in the anode. However, the fuel cell power output is still lower than that of Ni-modified Sr2Fe1.5Mo0.5O6-δ prepared by an infiltration method reported in our previous work. It is mainly due to the different amount of effective metal catalysts.

Figure 6. Electrical conductivity of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ (solid) and Sr2Fe1.5Mo0.5O6-δ (open).

Figure 7. (a) I-V and I-P curves and (b) impedance spectra of Sr1.9Fe1.4Ni0.1Mo0.5O6-δ-SDC anode tested in H2 (3 vol% H2O) at 700, 750 and 800°C with LSGM electrolyte and LSCF cathode.
in the anodes. Extracting all Ni from Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$ only yields 1 wt% of Ni in the anode and considering the observation of Ni-Fe alloy the portion of reduced metal Ni should be even smaller for Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$ in this work. Additionally, the formation of alloy may also result in different catalytic activity comparing with the single metal phase.

Stability of Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$-SDC was investigated by operating the fuel cell under a constant current load in H$_2$ at 800°C. The voltage dependence on time is shown in Figure 8. Similar to other material systems which can generate nano metal particles upon reduction in anode conditions, a gradual increase in cell performance was observed in the first 60 h for the Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$-SDC anode, probably due to the accumulation of metal catalysts on the surface. After reaching the maximum cell power output, the cell performance degraded at a very low rate. Similar degradation behavior was also reported for La$_{0.8}$Sr$_{0.2}$Cr$_{1-x}$O$_3$, $X$ = Ni and Ru, and Ni in which a high coarsening rate of the nanosized metal particles was thought to cause the performance degradation. However, the fluffy surface on the reduced Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$ as well as the formation of alloy may account for the slower degradation rate observed in this study for inhibiting the growth of metal particles.

Impedance spectra of the cell before and after the galvanostatic test were recorded under open circuit conditions in H$_2$ and the Nyquist plots are shown in Figure 9. It can be seen that the high frequency arc decreased slightly while the low frequency arc increased slightly after the test. As long as the metal alloy gradually accumulated on the surface in H$_2$, the H$_2$ adsorption/desorption and charge transfer may be further facilitated. This may account for the decrease of the high frequency polarization resistance. For the enlarged low frequency arc in the impedance spectra, it may be related to the coarsening of metal particles as reported for other material systems. Another possible reason may be the blockage of gas diffusion passages by Sr-riched phase from reduction. However, the overall change in the impedance spectra after the stability test was subtle, indicating good cell performance stability of the composite anode.

Redox stability of Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$-SDC anode was investigated at 800°C by switching the fuel gas between H$_2$ and air. After each cycle, the fuel cell was operated under a galvanostatic condition in H$_2$ for about 1 h and the impedance spectra were recorded. The change on time of cell voltage and resistances determined from the impedance spectra during five redox cycles are shown in Figure 10. It can be observed that the cell voltage in H$_2$ under a current load was even improved after 5 cycles when compared with the initial value. During two of the redox cycles, the anode was exposed to air for almost 20 h but the cell performance was found not sensitive to the anode exposure time in air. From the resistance results shown in Figure 10, it can be also seen that the major change was from the polarization resistance which also dominated the overall cell impedance while the ohmic resistance wasn’t affected by the redox cycling. The polarization resistance decreased after the fuel cell being operated in H$_2$ for 1 h in each cycle, indicating the re-established metal phase plays an important role in improving the single cell performance. Obviously, the polarization resistance decreased after five redox cycles as shown in Figure 10. It was consistent with those reported elsewhere that the redox cycling may help regenerating the nano-sized metal phase on the ceramic oxide. Generally speaking, Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$-SDC anode showed excellent stability during redox cycling.

Since Ni-Fe anode has been demonstrated to have good performance in propane, the anode performance of Sr$_{1.9}$Fe$_{1.4}$Ni$_{0.1}$Mo$_{0.5}$O$_{6.3}$-SDC in propane was also investigated. The initial cell peak power density only reached 227 mW cm$^{-2}$ at 800°C as shown in Figure 11a. A huge low frequency arc was observed in the impedance spectra in Figure 11b, indicating that the cell performance was limited by gas diffusion. The cell was operated under a current load of 300 mA cm$^{-2}$ for about 18 h and a substantial amount of liquid oil products was detected at the anode exhaust outlet. These longer chain hydrocarbons may be produced by dehydrogenation of propane. Interestingly, the OCV was improved from 1.08 V to 1.14 V temporarily after the galvanostatic test and cell performance were. Similar phenomenon in propane has also been reported for

other anode materials. The cell peak power density reached 324 mW cm⁻². The cell power output is still much lower than the Ni-Fe anode reported in the literature probably due to the low content of the metal catalysts generated on Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ anode under the SOFC operating conditions. This composition showed sufficient electrical conductivity as an SOFC anode. Due to the improved catalytic activity by the metal nanoparticles, Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ anode showed excellent cell performance in H₂ and its performance was quite stable. The anode performance of Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ-SDC can also be regenerated upon redox cycling and Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ has excellent redox stability. Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ-SDC anode also showed reasonable cell performance when propane was used as fuel. This study indicates that Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ is a very promising alternative anode material with enhanced catalytic activity and excellent redox stability inherited from the parent material SrFe₁.₉Mo₀.₅O₆⁻δ for solid oxide fuel cells.

Conclusions

Ni-Fe alloy nano particles were generated on the Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ anode under the SOFC operating conditions. This composition showed sufficient electrical conductivity as an SOFC anode. Due to the improved catalytic activity by the metal particles, Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ-SDC anode showed excellent cell performance in H₂ and its performance was quite stable. The anode performance of Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ-SDC can also be regenerated upon redox cycling and Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ has excellent redox stability. Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ-SDC anode also showed reasonable cell performance when propane was used as fuel. This study indicates that Sr₁.₉Fe₁.₄Ni₀.₁Mo₀.₅O₆⁻δ is a very promising alternative anode material with enhanced catalytic activity and excellent redox stability inherited from the parent material SrFe₁.₉Mo₀.₅O₆⁻δ for solid oxide fuel cells.
