ON THE CONVERGENCE OF GREEDY ALGORITHMS FOR INITIAL SEGMENTS OF THE HAAR BASIS

S. J. DILWORTH, E. ODELL, TH. SCHLUMPRECHT, AND ANDRÁS ZSÁK

Abstract. We consider the X-Greedy Algorithm and the Dual Greedy Algorithm in a finite-dimensional Banach space with a strictly monotone basis as the dictionary. We show that when the dictionary is an initial segment of the Haar basis in $L_p[0,1]$ ($1 < p < \infty$) then the algorithms terminate after finitely many iterations and that the number of iterations is bounded by a function of the length of the initial segment. We also prove a more general result for a class of strictly monotone bases.

1. Introduction

Greedy algorithms in Hilbert space are known to have good convergence properties. The first general result in this direction was obtained by Huber [6], who proved convergence of the Pure Greedy Algorithm (PGA) in the weak topology of a Hilbert space $H$ and conjectured that the PGA converges strongly in $H$. Huber’s conjecture was proved by Jones [7].

Our interest in this paper is in convergence results for greedy algorithms in a Banach space $X$ (see [12]). We say that $D \subset X$ is a dictionary if the linear span of $D$ is norm-dense in $X$ and $\|\varphi\| = 1$ for all $\varphi \in D$. (Usually, but not here, $D$ is also assumed to be symmetric.)

For some of the algorithms that have been proposed, e.g. the Weak Chebyshev Dual Greedy Algorithm [11, 2] or the Weak Greedy Algorithm with Free Relaxation [13], it is known that uniform smoothness of $X$ guarantees strong convergence of these algorithms for an arbitrary dictionary $D$. Rate of convergence results have also been proved [11, 13].

Key words and phrases. greedy algorithms; Banach spaces; Haar basis.

The first three authors were supported by the NSF.
We are mainly concerned with two natural generalizations of the PGA to the Banach space setting, namely the \textit{X-Greedy Algorithm} (XGA) and the \textit{Dual Greedy Algorithm} (DGA) (see [12]). These algorithms generate a sequence of greedy approximants \((G_n)\) to an initial vector \(x\). The updated approximant \(G_{n+1}\) is obtained from \(G_n\) by best one-term approximation of the residual \(x - G_n\) in the direction of a particular dictionary element \(\varphi_n \in \mathcal{D}\) which satisfies a certain selection criterion. Precise definitions will be given below.

Livshits [8] constructed a dictionary in a smooth Banach space for which the XGA fails to converge. No general convergence results for the strong topology are known for the XGA and the DGA for the class of uniformly smooth Banach spaces. In [3] convergence was proved (for an arbitrary dictionary) for the weak topology in uniformly smooth Banach spaces with the so-called \textit{WN Property}. In particular, weak convergence was proved in uniformly smooth Banach spaces which are uniformly convex and have a 1-unconditional basis. Unfortunately, \(L_p[0,1]\) (\(p \neq 2\)) does not enjoy the WN Property, so these results cannot be applied to \(L_p[0,1]\).

An important advance was made by Ganichev and Kalton [4] who proved strong convergence of the DGA in \(L_p[0,1]\) for an arbitrary dictionary. More precisely, they introduced a geometrical property called Property \(\Gamma\), proved strong convergence of the DGA in Banach spaces with Property \(\Gamma\), and showed that all subspaces of quotient spaces of \(L_p[0,1]\) (\(1 < p < \infty\)) enjoy Property \(\Gamma\). In [5] property \(\Gamma\) was characterized via the notion of a ‘tame’ convex function, and using this characterization several other important spaces were shown to enjoy Property \(\Gamma\).

The arguments used by Ganichev and Kalton do not seem to yield convergence results for the XGA. In particular, convergence of the XGA in \(L_p[0,1]\) is an open question. This is surprising because the XGA yields the best one-term approximation at each step. Even for the important special case of this problem in which the dictionary is the Haar basis of \(L_p[0,1]\) very little seems to be known.
Problem 1.1. Suppose the dictionary is the Haar basis in $L_p[0,1]$ ($p \neq 2$). Does the XGA converge strongly to the initial vector $x$? Does it converge in the weak topology?

We attacked the finite-dimensional analog of this problem and obtained the following theorem, which is a corollary of our main result (Theorem 3.6 below).

**Theorem 1.2.** Let $1 < p < \infty$ and let $(h_i^{(p)})_{i=0}^{\infty}$ be the normalized Haar basis for $L_p[0,1]$. Then, for each $m \geq 0$, there exists a positive integer $N(p,m)$ such that, for the dictionary $(h_i^{(p)})_{i=0}^{m}$, the XGA and DGA terminate in at most $N(p,m)$ iterations for every initial vector in the linear span of $(h_i^{(p)})_{i=0}^{m}$.

We present an example of a non-monotone basis of the two-dimensional Euclidean space for which the XGA does not terminate. When the dictionary is a strictly monotone finite basis we show that for every initial vector the XGA and DGA terminate after finitely many iterations. To get a uniform bound on the number of iterations that is independent of the initial vector as in Theorem 1.2 we isolate a particular property (Property P) of the Haar basis and prove the existence of a uniform bound for all strictly monotone bases with Property P.

The paper is organized as follows. The greedy algorithms which we consider are defined in the next section. Our main result is proved in Section 3. The final section contains two estimates for the Haar basis which lead to a refinement of Theorem 1.2 in the range $p > 2$.

## 2. Definitions and Notation

First we recall some notation and terminology from Banach space theory. We denote the unit sphere $\{x \in X : \|x\| = 1\}$ of $X$ by $S_X$. We say that $F_x \in X^*$ is a *norming functional* for a nonzero $x \in X$ when $\|F_x\|_{X^*} = 1$ and $F_x(x) = \|x\|$; by the Hahn-Banach theorem, each $x \in X$ has at least one norming functional. $X$ is smooth if $F_x$ is unique.

It is known that the norm of a smooth finite-dimensional Banach space is *uniformly Fréchet differentiable*, i.e.

\[
\|x + y\| = 1 + F_x(y) + \varepsilon(x,y)\|y\|
\]
for all \( x, y \in X \) with \( \|x\| = 1 \), where \( \varepsilon(x, y) \to 0 \) uniformly for \( (x, y) \in S_X \times X \) as \( \|y\| \to 0 \).

A basis \((e_i)_{i=1}^m\) of an \( m \)-dimensional Banach space \( X \) is said to be strictly monotone if

\[
\| \sum_{i=1}^{i_0} a_i e_i \| \leq \| \sum_{i=1}^m a_i e_i \|
\]

for all \( 1 \leq i_0 < m \) and \((a_i) \subset \mathbb{R}\) with equality only if \( a_i = 0 \) for \( i = i_0 + 1, \ldots, m \). The dual basis \((e^*_i)_{i=1}^m \subset X^*\) is defined by \( e^*_i(e_j) = \delta_{i,j} \). The basis is normalized if \( \|e_i\| = 1 \) for \( i = 1, \ldots, m \). Note that if \((e_i)_{i=1}^m\) is a normalized (strictly) monotone basis then for all \((a_i) \subset \mathbb{R}\), we have

\[
\frac{1}{2} \max_{1 \leq i \leq m} |a_i| \leq \| \sum_{i=1}^m a_i e_i \| \leq \sum_{i=1}^m |a_i|.
\]

Let us recall the definition of the Haar basis functions defined on \([0, 1]\). Let \( h_0 \equiv 1 \). For \( n \geq 0 \) and \( 0 \leq k < 2^n \), we define \( h_i \) for \( i = 2^n + k \) thus:

\[
h_i = \begin{cases} 
1 & \text{on } [k/2^n, (2k + 1)/2^{n+1}) \\
-1 & \text{on } [(2k + 1)/2^{n+1}, (k + 1)/2^n) \\
0 & \text{elsewhere.}
\end{cases}
\]

The Haar basis is a strictly monotone basis of \( L_p[0, 1] \) (equipped with its usual norm \( \| \cdot \|_p \)) for \( 1 < p < \infty \).

The algorithms which we consider in this paper all arise from the repeated application of a greedy step to a nonzero residual vector \( y \in X \). Let us describe the general form of this greedy step.

(i) Select \( \varphi(y) \in \mathcal{D} \) by applying a selection procedure (which depends on the particular algorithm in question) to \( y \). In general the selection procedure will allow many possible choices for \( \varphi(y) \).

(ii) Then select \( \lambda(y) \in \mathbb{R} \) to minimize \( \|y - \lambda \varphi(y)\| \) over \( \lambda \).

Starting with an initial vector \( x \in X \), we generate a sequence of residuals \((x_n)\) as follows.

(i) Set \( x_0 := x \).

(ii) For \( n \geq 1 \), apply the greedy step to the residual \( y = x_{n-1} \) to obtain \( \varphi_n := \varphi(x_{n-1}) \in \mathcal{D} \) and \( \lambda_n := \lambda(x_{n-1}) \in \mathbb{R} \).

(iii) Set \( x_n := x_{n-1} - \lambda_n \varphi_n \) to be the updated residual.
The algorithm is said to converge (strongly) if \( \|x_n\| \to 0 \) as \( n \to \infty \). It is said to terminate after \( N \) steps if \( x_N = 0 \). For \( n \geq 1 \), the \( n \)th greedy approximant is defined by \( G_n = \sum_{i=1}^{n} \lambda_i \varphi_i \). Note that \( G_n = x - x_n \) and that \( x = \sum_{i=1}^{\infty} \lambda_i \varphi_i \) (resp. \( x = \sum_{i=1}^{N} \lambda_i \varphi_i \)) if the algorithm converges (resp. terminates after \( N \) steps).

Two important greedy algorithms of this type are the weak \( X \)-Greedy Algorithm (WXGA) and Weak Dual Greedy Algorithm (WDGA) (see [12]). In both cases a weakness parameter \( \tau \in (0, 1) \) is specified in advance. For the WXGA with weakness parameter \( \tau \) the greedy step is as follows. Given a nonzero \( x \in X \), we select \( \varphi \in \mathcal{D} \) to satisfy

\[
\|x\| - \min_{\lambda \in \mathbb{R}} \|x - \lambda \varphi(x)\| \geq \tau \left( \|x\| - \inf_{\varphi \in \mathcal{D}} \|x - \lambda \varphi\| \right).
\]

We can also set \( \tau = 1 \) in the above when it can be shown that the infimum in (3) is attained, e.g. if \( \mathcal{D} \) is finite or if \( \mathcal{D} \) is a monotone basis for \( X \); the case \( \tau = 1 \) is the \( X \)-Greedy Algorithm (XGA) discussed in the Introduction.

For the WDGA with weakness parameter \( \tau \) the greedy step is as follows. Given a nonzero \( y \in X \), choose \( \varphi(y) \in \mathcal{D} \) such that

\[
|F_y(\varphi(y))| \geq \tau \sup_{\varphi \in \mathcal{D}} |F_y(\varphi)|.
\]

The case \( \tau = 1 \), when it makes sense, is the Dual Greedy Algorithm (DGA) discussed in the Introduction. Smoothness of \( X \) guarantees that the residuals satisfy \( \|x_n\| < \|x_{n-1}\| \) for both the WXGA and the WDGA.

### 3. Main Results

**Proposition 3.1.** Suppose that \( X \) is a finite-dimensional smooth Banach space. Then there exists \( \gamma \in (0, 1) \) such that the greedy steps of both the WXGA and WDGA applied to any nonzero \( y \in X \) satisfy

\[
\|y - \lambda(y) \varphi(y)\| \leq \gamma \|y\|.
\]

**Proof.** First we consider the WDGA with weakness parameter \( \tau \). By compactness of \( S_X \) and continuity of the mapping \( y \to F_y \), there exists \( \delta > 0 \) such that

\[
\sup\{ |F_y(\phi)| : \phi \in \mathcal{D} \} \geq \delta \quad (y \in S_X).
\]
Hence, the WDGA applied to \( y \in S_X \) selects \( \varphi(y) \in D \) such that 
\[ |F_y(\varphi(y))| \geq \tau \delta. \]
By uniform Fréchet differentiability of the norm there exists \( \eta > 0 \) such that for all \( y \in S_X \) and for all \( z \in X \) with \( \|z\| \leq \eta \), we have \( |\varepsilon(y, z)| \leq \tau \delta / 2 \) in (1), and hence
\[
\|y - z\| = 1 - F_y(z) + \varepsilon(y, -z)\|z\| \\
\leq 1 - F_y(z) + \frac{\tau \delta}{2} \eta.
\]
Setting \( z = \pm \eta \varphi(y) \) for the appropriate choice of signs yields \( F_y(z) \geq \eta \tau \delta \), and hence
\[
\|y - z\| \leq 1 - \frac{\eta \tau \delta}{2}.
\]
By homogeneity we get for all nonzero \( y \in X \)
\[
(5) \quad \|y - \lambda(y) \varphi(y)\| \leq (1 - \frac{\eta \tau \delta}{2})\|y\|.
\]
Setting \( \tau = 1 \) in the above yields an estimate for the DGA. Since the greedy step of the XGA produces a residual with the smallest norm, it follows that the same estimate must also hold for the XGA. But this implies that (5) also holds for the WXGA with parameter \( \tau \).

We turn now to consider the case in which \( X \) is \( m \)-dimensional \((1 \leq m < \infty)\) and the dictionary is a strictly monotone normalized basis 
\( B = (e_i)_{i=1}^m \) for \( X \). We shall say that the algorithm is *norm-reducing with constant \( \gamma \) \((0 < \gamma < 1)\) if (4) holds for the greedy step.

**Proposition 3.2.** Suppose that the algorithm is norm-reducing with constant \( \gamma \). Then, for each initial vector \( x \in X \), the algorithm terminates after finitely many steps.

Proof. The proof is by induction on \( m \). The result is trivial if \( m = 1 \), so suppose \( m > 1 \) and that \( x = \sum_{i=1}^m a_i e_i \). If \( a_m = 0 \), then by monotonicity of \( B \) the algorithm will never select \( e_m \), so the result follows by induction. So suppose that \( a_m \neq 0 \). If the algorithm selects \( e_m \) at the \( n^{th} \) step, then by strict monotonicity the new residual \( x_n \) satisfies \( e_m^*(x_n) = 0 \), i.e. the last coefficient is set equal to zero, and the result follows by induction. Thus to conclude the proof it suffices
to show that $e_m$ is eventually selected. But if $e_m$ is never selected then
$e^*_m(x_n) = a_m$ for all $n \geq 1$, so by (2)
$$\gamma^n \|x\| \geq \|x_n\| \geq \frac{1}{2} \max_{1 \leq i \leq m} |e^*_i(x_n)| \geq \frac{|a_m|}{2},$$
which is a contradiction when $n$ is larger than $\ln(2\|x\|/|a_m|) / \ln(\gamma^{-1})$.

\[ \square \]

**Example 3.3.** Monotonicity of the basis is essential. Indeed, consider
the basis $B = \{(1, 0), (1/\sqrt{2}, 1/\sqrt{2})\}$ of 2-dimensional Euclidean space.
It is easily seen that the XGA does not terminate unless the initial
vector is a multiple of one of the basis vectors.

**Problem 3.4.** The estimate $n \leq \ln(2\|x\|/|a_m|) / \ln(\gamma^{-1})$ for the num-
ber of steps before the algorithm terminates clearly depends on $x$ and
becomes unbounded as $a_m \to 0$. Is there a uniform bound $N$ which is
independent of the initial vector $x$?

We shall now provide a sufficient condition which guarantees a positive answer to this question. Then we verify that the initial segments
of the Haar basis satisfy this condition.

**Definition 3.5.** Let $B = (e_i)_{i=1}^m$ be a normalized monotone basis for $X$.
We say that $B$ has *Property P with constant $\zeta > 0$* if the following
condition is satisfied: for all $x = \sum_{i=1}^m a_i e_i \in X$ and for all $1 \leq i_0 \leq m - 1$, we have
$$|t_0| \leq \zeta \sum_{i=i_0+1}^m |a_i|,$$
where $t_0$ minimizes the mapping $t \mapsto \| \sum_{i=1}^{i_0} a_i e_i + te_{i_0} + \sum_{i=i_0+1}^m a_i e_i \|.$

Now we can state our main result.

**Theorem 3.6.** Suppose that $X$ is $m$-dimensional, that $B$ is a strictly
monotone basis for $X$ which has Property P with constant $\zeta$, and that
the algorithm is norm-reducing with constant $\gamma$. Then there exists a
positive integer $N(m, \gamma, \zeta)$ such that the algorithm terminates in at
most $N$ steps for every initial vector $x \in X$.

The proof of Theorem 3.6 requires some combinatorial notation which
we shall now describe. For positive integers $r$ and $s$, with $r \leq s$, the
integer interval \( \{n \in \mathbb{N} : r \leq n \leq s \} \) will be denoted by \([r, s]\). If \(I_1\) and \(I_2\) are integer intervals we write \(I_2 < I_1\) if \(\max I_2 < \min I_1\), and we say they are consecutive if \(\min I_1 = \max I_2 + 1\).

For \(1 \leq k \leq m\), an interval partition of \([1, m]\) is a \(k\)-tuple \(P = (I_1, \ldots, I_k)\) of consecutive integer intervals \(I_1, \ldots, I_k\) such that \(\min I_k = 1\), \(\max I_1 = m\), and \(I_k < I_{k-1} < \cdots < I_1\). The collection \(\mathcal{P}(m)\) of all interval partitions of \([1, m]\) is readily seen to have cardinality \(2^{m-1}\). We endow \(\mathcal{P}(m)\) with the lexicographical ordering \(\prec\), i.e., if \(P_1 = (I_1, \ldots, I_k)\) and \(P_2 = (J_1, \ldots, J_s)\) are two interval partitions then \(P_1 \prec P_2\) if, for some \(t \geq 1\), we have \(\text{card } I_u = \text{card } J_u\) for \(1 \leq u < t\) and \(\text{card } I_t < \text{card } J_t\). Note that \(([1, m])\) is the maximum element of \((\mathcal{P}(m), \prec)\).

Next we associate to each \(y = \sum_{i=1}^{m} a_i e_i \in X\) an interval partition \(P(y) = (I_1, \ldots, I_k) \in \mathcal{P}(m)\) by ‘backwards induction’ as follows:

(i) \(m \in I_1\);

(ii) Suppose that \(1 \leq i < m\) and that \(i + 1 \in I_j\). Then

\[
i \in \begin{cases} I_j & \text{if } |a_i| \leq (1 + \zeta)^{m-i} \sum_{r=1}^{j} |a_{\max I_r}|, \\ I_{j+1} & \text{otherwise}. \end{cases}
\]

It may be helpful to explain the intuition behind this definition. The definition of \(P(y)\) begins with \(I_1\). Working backwards from \(i = m \in I_1\), then \(i\) is placed in the same interval \(I_j\) as \(i + 1\) if the coefficient \(|a_i|\) is not too much larger (roughly speaking) than the later coefficients \(|a_{i+1}|, \ldots, |a_m|\). But if \(|a_i|\) is much larger than the later coefficients then a new interval \(I_{j+1}\) is begun for which \(i = \max I_{j+1}\). Note that

\[
\|y\| \leq \sum_{i=1}^{m} |a_i| = \sum_{j=1}^{k} \sum_{i \in I_j} |a_i| \leq \left( \sum_{j=1}^{k} |a_{\max I_j}| \right) \sum_{i=1}^{m} (1 + \zeta)^{m-i} \leq m \frac{(1 + \zeta)^m}{\zeta} \max_{1 \leq j \leq k} |a_{\max I_j}|.
\]
Lemma 3.7. For each initial vector $y \in X$ with $P(y) = (I_1, \ldots, I_k)$ there exists $i_0 \in \{\max I_j: 1 \leq j \leq k\}$ such that the algorithm selects $e_{i_0}$ in at most $n_0$ steps, where

$$n_0 \leq 1 + \left\lfloor \frac{\ln(2m(1 + \zeta)^m/\zeta)}{\ln(1/\gamma)} \right\rfloor.$$  

Proof. Let $i_0$ be defined by

$$|a_{i_0}| = \max\{|a_i|: i \in \{\max I_j: 1 \leq j \leq k\}\}.$$  

Suppose that $e_{i_0}$ is first selected at the $(n_0)$th step. Then the residual $y_{n_0-1}$ satisfies by (2) and (7)

$$\frac{|a_{i_0}|}{2} \leq \|y_{n_0-1}\| \leq \gamma^{n_0-1}\|y\| \leq \gamma^{n_0-1}m(1 + \zeta)^{m-1} |a_{i_0}|,$$

and the result follows. \hfill \Box

Lemma 3.8. Suppose that when applied to $y$ the algorithm selects $e_{i_0}$ and produces a residual $z$. Let $P(y) = (I_1, \ldots, I_k)$ and $P(z) = (J_1, \ldots, J_l)$. Then either $i_0 = m$ or

$$P(y) \begin{cases} < P(z) & \text{if } i_0 \in \{\max I_j: 2 \leq j \leq k\}, \\ = P(z) & \text{otherwise}. \end{cases}$$

Proof. We may assume that $i_0 < m$. Suppose that $i_0 + 1 \in J_{j_0}$. Let $y = \sum_{i=1}^{m} a_i e_i$ and $z = \sum_{i=1}^{m} b_i e_i$. Clearly, $b_i = a_i$ if $i \neq i_0$. Thus by (6), $J_j = I_j$ for $j < j_0$ and $\max J_{j_0} = \max I_{j_0}$. Since $B$ has Property P with constant $\zeta$, and using the estimate $|a_i| \leq (1 + \zeta)^{m-i}(\sum_{j=1}^{j_0} |a_{\max I_j}|)$ for $i > i_0$ which follows from (6), we get

$$|b_{i_0}| \leq \zeta \sum_{i=i_0+1}^{m} |a_i|$$

$$\leq \zeta (\sum_{i=i_0+1}^{m} (1 + \zeta)^{m-i})(\sum_{j=1}^{j_0} |a_{\max I_j}|)$$

$$\leq (1 + \zeta)^{m-i_0}(\sum_{j=1}^{j_0} |b_{\max J_j}|).$$

Thus, by (6), $i_0 \in J_{j_0}$. In particular, if $i_0 \notin I_{j_0}$ (in which case $i_0 = \max I_{j_0+1}$), then $\text{card}(J_{j_0}) > \text{card}(I_{j_0})$, so $P(y) < P(z)$. On the other hand, if $i_0 \in I_{j_0}$, then using the facts that $b_i = a_i$ if $i \neq i_0$ and that $i_0 \neq \max J_{j_0}$, it follows again from (6) that $P(y) = P(z).$ \hfill \Box
Proof of Theorem 3.6. The proof is by induction on $m$. Let $x \in X$. We may assume that $e_m^*(x) \neq 0$. It suffices to give a bound independent of $x$ for the number of steps required for the algorithm to select $e_m$. Let $P(x) = (I_1, \ldots, I_k)$. Then by Lemma 3.7 the algorithm selects either $e_m$ or $e_i$, where $i_0 \in \{\max I_j : 2 \leq j \leq k\}$, in at most $n_0$ steps. In the latter case, by Lemma 3.8, $P(x) \prec P(x_{n_0})$. Repeating the argument with $x$ replaced by $x_{n_0}$, we find that either $e_m$ is selected in the first $2n_0$ steps or $P(x_{n_0}) \prec P(x_{2n_0})$. After a total of at most $\text{card}(P(m)) - 1 = 2^m - 1$ iterations of this argument, we find that either $e_m$ is selected in the first $(2^m - 1)n_0$ steps or $P(x_{(2^m - 1)n_0}) = ([1, m])$, the maximum element of $P(m)$. In the latter case, by Lemma 3.7, $e_m$ will be selected in at most a further $n_0$ steps. In conclusion, $e_m$ will be selected in at most $(2^m - 1)n_0$ steps. This leads to the estimate

\begin{equation}
N(m, \gamma, \zeta) = n_0 \sum_{i=1}^{2^m - 1} = (2^m - 1)n_0.
\end{equation}

\[ \square \]

Our next goal is to show that all initial segments of the Haar basis for $L_p[0, 1] (1 < p < \infty)$ have property $P$ with constant $\zeta$ depending on $m$ and $p$. In the next section we prove that if $p > 2$ then $\zeta$ may be chosen independently of $m$.

Lemma 3.9. Let $1 < p < \infty$ and let $h_i^{(p)} = h_i/\|h_i\|_p$ ($i \geq 0$). For each $m \geq 1$ there exists a positive constant $C(m, p)$ such that, for all $M \in \mathbb{R}$, if $|a_1| \geq C(m, p) \sum_{j=2}^{m} |a_j|$, then

\begin{equation}
\|M + \sum_{i=1}^{m} a_i h_i^{(p)}\|_p \geq \|M + \sum_{i=2}^{m} a_i h_i^{(p)}\|_p.
\end{equation}

Proof. If $M = 0$ we can take $C(m, p) = 2$ by an easy triangle inequality calculation. If $M \neq 0$ then by homogeneity of the norm we may assume that $M = 1$. By expanding in a Taylor series, we see that there exist positive constants $b_1, \ldots, b_m$ such that

\begin{align*}
\|1 + \sum_{i=1}^{m} a_i h_i^{(p)}\|_p^p &= \int_0^1 |1 + \sum_{i=1}^{m} a_i h_i^{(p)}|^p dt \\
&= 1 + \sum_{i=1}^{m} b_i a_i^2 + o(\sum_{i=1}^{m} a_i^2).
\end{align*}
Thus there exists $0 < \varepsilon < 1$ such that if $|a_1| = \sum_{i=2}^m |a_i| < \varepsilon$ then (10) is satisfied. By convexity of the mapping
\[
t \mapsto \|1 + th^{(p)}_1 + \sum_{i=2}^m a_i h^{(p)}_i\|_p,
\]
it follows that (10) is also satisfied whenever $\sum_{i=2}^m |a_i| < \varepsilon$ and $|a_1| \geq \sum_{i=2}^m |a_i|$. Now suppose that $\sum_{i=2}^m |a_i| \geq \varepsilon$. If
\[
|a_1| \geq (2 + 2/\varepsilon) \sum_{i=2}^m |a_i| \geq 2 + 2 \sum_{i=2}^m |a_i|,
\]
then by the triangle inequality
\[
\|1 + \sum_{i=1}^m a_i h^{(p)}_i\|_p \geq |a_1| - 1 - \sum_{i=2}^m |a_i|
\geq 2 + 2 \sum_{i=2}^m |a_i| - 1 - \sum_{i=2}^m |a_i|
= 1 + \sum_{i=2}^m |a_i|
\geq \|1 + \sum_{i=2}^m a_i h^{(p)}_i\|_p.
\]
Thus, $C(m, p) = 2 + 2/\varepsilon$ works.

\[\square\]

**Proposition 3.10.** Let $1 < p < \infty$. For each $m \geq 1$, the initial segment $(h^{(p)}_i)_{i=0}^m$ of the Haar basis for $L_p[0,1]$ has property P with constant $\zeta = C(m, p)$.

**Proof.** Let $0 \leq i_0 < m$. Suppose $t_0$ minimizes the function
\[
t \mapsto \| \sum_{i=0}^{i_0-1} a_i h^{(p)}_i + th^{(p)}_{i_0} + \sum_{i=i_0+1}^m a_i h^{(p)}_i \|
\]
for fixed coefficients $(a_i) \subset \mathbb{R}$. Suppose that $h_{i_0}$ is supported on the dyadic interval $I$ and let $M$ be the (constant) value assumed by $\sum_{i=0}^{i_0-1} a_i h^{(p)}_i$ on $I$. Then $t_0$ minimizes the function
\[
t \mapsto \int_I |M + th^{(p)}_{i_0} + \sum_{i=i_0+1}^m a_i h^{(p)}_i|^p \, dx.
\]
Lemma 3.9 obviously transfers from \([0, 1]\) to \(I\). So

\[ |t_0| \leq C(p, m) \sum_{i_0+1}^{m} |a_i|. \]

\[ \square \]

Note that in view of the preceding result the initial segments of the Haar basis in \(L_p[0, 1]\) satisfy the hypotheses of Theorem 3.6. Thus, Theorem 1.2 is a special case of Theorem 3.6.

4. Further Results

In this section we present some more precise estimates for the Haar basis. First we estimate the norm-reducing constant \(\gamma\). Then we show that for \(p > 2\) the constant \(\zeta\) for Property \(P\) may be chosen to be independent of \(m\).

Recall that the modulus of smoothness \(\rho_X(t)\) of a Banach space \(X\) is defined for \(0 < t \leq 1\) by

\[ \rho_X(t) = \sup \left\{ \frac{\|x + y\| + \|x - y\|}{2} - 1 : x, y \in X, \|x\| = 1, \|y\| = t \right\} \]

(see [9, p. 59]). The modulus of smoothness for \(L_p[0, 1]\) satisfies

\[ \rho_{L_p[0,1]}(t) \leq \begin{cases} c_p t^p & \text{if } 1 < p \leq 2, \\ c_p t^2 & \text{if } 2 < p < \infty, \end{cases} \]

where \(c_p\) is a constant (see [9, p. 63]).

**Proposition 4.1.** Suppose that \(m \geq 1\) and that \(A \subseteq \mathbb{N}\) has cardinality \(m\). For \(D_A := (h_i^{(p)})_{i \in A}\) and \(X_A := \text{span } D_A \subset L_p[0, 1]\) we have that the DGA and XGA are norm-reducing with constant

\[ \gamma \leq \begin{cases} 1 - c'_p m^{p/(2-2p)} & \text{if } 1 < p \leq 2, \\ 1 - c'_p m^{(2-2p)/p} & \text{if } 2 < p < \infty, \end{cases} \]

where \(c'_p\) is a constant depending only on \(p\).

**Proof.** The XGA produces the greatest norm reduction at each step, so it suffices to prove the result for the DGA. For convenience let \(c\) denote a constant depending only on \(p\) whose precise value may change from
line to line. First we consider the case $1 < p \leq 2$. Let $y = \sum_{i \in A} a_i h_i^{(p)} \in S_{X_A}$ and let $F_y = \sum_{i \in A} b_i h_i^{(q)} \in S_{X_A}^*$, where $q = p / (p - 1)$. Note that
\[
\|F_y\|_q \geq \|F_y\|_{X_A}^* = 1.
\]
The Haar basis in $L_q[0,1]$ satisfies an upper 2-estimate for $q > 2$ (see [1]). Thus, $\sum_{i \in A} |b_i|^2 \geq c$, and since card $A = m$ we get
\[
|b_{i_0}| : = \max_{i \in A} |b_i| \geq c \sqrt{m}.
\]
We may assume that $b_{i_0} > 0$. Thus, for $t \geq 0$, we have
\[
\|y + th_{i_0}^{(p)}\|_p \geq F_y(y + th_{i_0}^{(p)}) = 1 + tb_{i_0} \geq 1 + \frac{ct}{\sqrt{m}}.
\]
Hence
\[
\|y - th_{i_0}^{(p)}\|_p \leq 2 - \|y + th_{i_0}^{(p)}\|_p + 2\rho_{L_p[0,1]}(t)
\]
\[
\leq 2 - (1 + \frac{ct}{\sqrt{m}}) + 2c_p t^p
\]
\[
= 1 - \frac{ct}{\sqrt{m}} + 2c_p t^p.
\]
Choosing $t$ to minimize $1 - (ct/\sqrt{m}) + 2c_p t^p$ yields $\gamma \leq 1 - cm^{p/(2-2p)}$. The case $p > 2$ is proved similarly using the fact that the Haar basis in $L_q[0,1]$ satisfies an upper $q$-estimate for $q < 2$. $\square$

**Proposition 4.2.** Suppose that $2 < p < \infty$. Then for all $y \in \text{span}(h_i)_{i=2}^\infty$, we have
\[
\|1 + t\|y\|_p h_1 + y\|_p \geq \|1 + y\|_p
\]
provided $|t| \geq \max(4, 2^{(p-3)/2} \sqrt{p(p-1)})$.

**Proof.** If $\|y\|_p > 1$ then the result holds for $|t| \geq 4$ by the triangle inequality. So assume $\|y\|_p \leq 1$. For $p \geq 2$, $f(x) = |x|^p$ is twice differentiable. Thus, by the Mean Value Theorem, for all $x \in \mathbb{R}$ there exists $0 < \theta(x) < 1$ such that
\[
|1 + x|^p = 1 + px + \frac{p(p-1)}{2} x^2 |1 + \theta(x)x|^{p-2}.
\]
Thus, for all $y \in \text{span}(h_i)_{i=2}^\infty$ with $\|y\|_p \leq 1$, we have
\[
\int_0^1 |1 + y(s)|^p \, ds \leq 1 + p \int_0^1 y(s) \, ds + \frac{p(p-1)}{2} \int_0^1 y(s)^2 |1 + |y(s)||^{p-2} \, ds
\]
\[
= 1 + 0 + \frac{p(p-1)}{2} \int_0^1 y(s)^2 |1 + |y(s)||^{p-2} \, ds
\]
\[
\leq 1 + \frac{p(p-1)}{2} \|y\|_p^2 \|1 + |y||^{p-2}
\]
(by Hölder’s inequality for the conjugate indices $p/2$ and $p/(p-2)$)
\[
\leq 1 + 2^{p-2} \left( \frac{p(p-1)}{2} \right) \|y\|_p^2,
\]
using the fact that $\|y\|_p \leq 1$ in the last line. Hence
\[
\|1 + y\|_p \leq (1 + 2^{p-2} p(p-1) \|y\|_p^2)^{1/p}.
\]

On the other hand, since $p > 2$, we have
\[
\|1 + t\|_p h_1^{(p)}(p) + y\|_p \geq \|1 + t\|_p h_1^{(p)} + y\|_2
\]
\[
\geq \|1 + t\|_p h_1^{(p)}\|_2
\]
\[
= (1 + t^2 \|y\|_p^2)^{1/2}.
\]

Combining (11) and (12) yields the result.

**Corollary 4.3.** Let $2 < p < \infty$. Every finite subsequence of the Haar basis for $L_p[0,1]$ has property $P$ with constant
\[
\zeta = \max(4, 2^{(p-3)/2} \sqrt{p(p-1)}).
\]

Combining Proposition 4.1 with Corollary 4.3, and using the estimates (8) and (9) for the number of iterations, yields the following strengthening of Theorem 1.2 in the range $p > 2$ in which the initial segment of the Haar basis of length $m$ is replaced by any subset of cardinality $m$.

**Theorem 4.4.** Let $2 < p < \infty$ and let $m \geq 1$. Then, for all $A \subset \mathbb{N}$ of cardinality $m$, the XGA and DGA terminate in at most $O(2^m m \ln m)$ iterations for the dictionary $D_A$ and for every initial vector in $X_A$.

**Remark 4.5.** We do not know whether or not the last result holds also for $1 < p < 2$.
